Abstract

Data from seven moorings deployed across the East Greenland shelfbreak and slope 280 km downstream of Denmark Strait are used to investigate the characteristics and dynamics of Denmark Strait Overflow Water (DSOW) cyclones. On average, a cyclone passes the mooring array every other day near the 900 m isobath, dominating the variability of the boundary current system. There is considerable variation in both the frequency and location of the cyclones on the slope, but no apparent seasonality. Using the year-long data set from September 2007 to October 2008, we construct a composite DSOW cyclone that reveals the average scales of the features. The composite cyclone consists of a lens of dense overflow water on the bottom, up to 300 m thick, with cyclonic flow above the lens. The azimuthal flow is intensified in the middle and upper part of the water column and has the shape of a Gaussian eddy with a peak depth-mean speed of 0.22 m/s at a radius of 7.8 km. The lens is advected by the mean flow of 0.27 m/s and self propagates at 0.45 m/s, consistent with the topographic Rossby wave speed and the Nof speed. The total translation velocity along the East Greenland slope is 0.72 m/s. The self-propagation speed exceeds the cyclonic swirl

¹Now at Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany

speed, indicating that the azimuthal flow cannot kinematically trap fluid in the water column above the lens. This implies that the dense water anomaly and the cyclonic swirl velocity are dynamically linked, in line with previous theory. Satellite sea surface temperature (SST) data are investigated to study the surface expression of the cyclones. Disturbances to the SST field are found to propagate less quickly than the in-situ DSOW cyclones, raising the possibility that the propagation of the SST signatures is not directly associated with the cyclones.

Keywords: Denmark Strait Overflow Water cyclone, East Greenland boundary current system, East Greenland Spill Jet, Deep Western Boundary Current

1. Introduction

The dense water passing southward through Denmark Strait comprises the largest contribution to the lower limb of the Atlantic meridional overturning circulation. As such, the mixing, entrainment, and precise pathways of the water south of the strait impact the global climate. While the mean equatorward flux of the dense water across the sill between Iceland and Greenland is fairly well estimated (Jochumsen et al., 2012), the detailed, time-dependent nature of the flow is not fully understood. The densest portion of the outflow from Denmark Strait (sill depth of 650 m) is called Denmark Strait Overflow Water (DSOW). Although the transport of DSOW appears to be relatively stable on seasonal to interannual timescales (Dickson and Brown, 1994; Macrander et al., 2005), the flow exhibits striking mesoscale variability with large changes in density and velocity (Worthington, 1969) occurring over periods of a few days (e.g. Macrander et al., 2007; Haine, 2010). It is essential to understand how such high frequency variability of the Denmark Strait overflow impacts the fate of the dense water downstream of the strait.

During its initial descent from the sill, the Denmark Strait overflow accelerates and entrains ambient water thereby reducing its density (Price and O’Neil Baringer, 1994). However, this modified water still contributes to the densest component of the North Atlantic

18 Deep Water (NADW) which ventilates a significant portion of the deep World Ocean. As
19 part of the adjustment process, the DSOW layer, as well as the overlying intermediate wa-
20 ter, stretches vertically. Due to potential vorticity constraints this induces positive relative
21 vorticity and leads to cyclone formation (Spall and Price, 1998). The dynamics associated
22 with the propagation of a lens of dense water on a sloping bottom have been addressed in
23 numerous studies.

24 The laboratory and numerical experiments of Whitehead et al. (1990) showed that a
25 cyclonic circulation exists vertically offset above the lens. Nof (1983) studied dense water
26 lenses on a sloping bottom that are associated with an anti-cyclonic flow around the lenses
27 at the same depth as the lenses and showed that they propagate at a speed proportional to
28 the density anomaly and the bottom slope. Swaters and Flierl (1991) developed a two layer
29 model of an isolated eddy which was later extended to include a stratified upper layer (Poulin
30 and Swaters, 1999). Such an isolated eddy does not depend upon far-field interactions to
31 be balanced as its pressure anomaly vanishes away from the eddy. This condition has
32 been formalized as the “Stern integral constraint” (Mory, 1985). If the interaction between
33 the lower dense water layer and the overlying water column is significant, then the model
34 of Swaters and Flierl (1991) predicts strong cyclonic flow in the upper layer and weak
35 azimuthal speeds in the deep layer consistent with Whitehead et al. (1990). In this case, the
36 propagation velocity of the lower layer lens is faster than the azimuthal speed in either layer,
37 but is still consistent with the “Nof speed”. On the East Greenland slope the propagating
38 lenses of overflow water with overlying cyclonic circulation are called “DSOW cyclones”.
39 In the model of Spall and Price (1998) the cyclones form from a steady outflow; however,
40 presently it is unknown how the time-dependent boluses of DSOW in the strait are related
41 to this cyclogenesis process.

42 [Figure 1 about here.]

43 Garton et al. (2001) observed the initial formation and descent of the DSOW cyclones

44 just south of the sill. Their subsequent evolution along the East Greenland slope was studied
45 with an idealized numerical model by Spall and Price (1998) and with realistically configured
46 simulations by Käse et al. (2003) and Magaldi et al. (2011). However, observational studies
47 of the cyclones downstream of the strait have been limited to two surface-based studies.
48 Krauss (1996) used the tracks of surface drifters drogued at 100 m depth to identify and de-
49 scribe three cyclonic features that moved equatorward along the East Greenland slope. The
50 measurements suggested a Gaussian eddy with a radius of 10 km that progressed southward
51 due to self-propagation as well as advection by the background current. Bruce (1995) used
52 satellite imagery to track disturbances (“hooks”, “spirals”, etc) to the sea surface tempera-
53 ture (SST) front between cold East Greenland Current water inshore of the shelfbreak and
54 warm Irminger Current water offshore of the shelfbreak. Based on 33 observations, Bruce
55 (1995) found that the features propagated southward at roughly 0.27 m/s which is somewhat
56 slower than what Krauss (1996) deduced. The inferred average radius was 17 km. Bruce
57 (1995) then compared the structures in SST with theoretical and laboratory studies (e.g.
58 Whitehead et al., 1990) and argued that the SST disturbances are the surface signature of
59 the DSOW cyclones.

60 The boundary current system along the East Greenland continental slope (schematically
61 shown in Figure 1) consists of three distinct components in addition to the variable flow
62 associated with the DSOW cyclones. The East Greenland/Irminger Current is a surface-
63 intensified flow supported by the horizontal density gradient between the Arctic-origin water
64 on the shelf and the warm (denser) North Atlantic-origin water on the slope (e.g. Sutherland
65 and Pickart, 2008; Brearley et al., 2012). The East Greenland Spill Jet (hereafter referred
66 to as the spill jet) is a bottom-intensified flow on the upper slope that is comprised of
67 dense waters that “spill” off the shelf south of Denmark Strait and subsequently adjust
68 to form a southward-flowing current (Pickart et al., 2005; Harden et al., 2013). Finally,
69 the Deep Western Boundary Current (DWBC) is the near-bottom equatorward flow that

70 transports the densest part of the NADW (Dickson and Brown, 1994). Interestingly, mooring
71 observations east of Cape Farewell (the southern tip of Greenland) have found no sign of
72 mesoscale variability similar to that of DSOW cyclones (Daniault et al., 2011; Bacon and
73 Saunders, 2010). This suggests that the DSOW cyclones spin-down during their transit
74 along the East Greenland slope.

75 The amount of entrainment of ambient water into the dense water overflow plume south
76 of Denmark Strait determines the final properties of the newly formed NADW. As such, it is
77 of high importance to understand and quantify the processes that dictate the evolution of the
78 flow during its adjustment along the East Greenland continental slope. In an effort to learn
79 more about the boundary current system in this region, a mooring array was deployed for
80 a one-year period approximately 280 km southwest of Denmark Strait. The array extended
81 from the outer-shelf to the deep slope and hence captured the East Greenland/Irminger
82 Current, the spill jet, and the shoreward portion of the DWBC. It also sampled the frequent
83 passage of DSOW cyclones which are the focus of this study. Using the mooring timeseries
84 we first present the statistics of the eddies, and then construct a composite cyclone using
85 the year-long data. In doing so we quantify the scales of the features, their downstream
86 propagation, and the associated pressure field. Finally, using satellite imagery, we investigate
87 the possible sea surface signature of the cyclones and compare this to the previous results
88 of Bruce (1995).

89 **2. Data**

90 *2.1. Mooring array*

91 The mooring array on the East Greenland shelf and slope consisted of seven moorings
92 deployed from 5 September 2007 to 4 October 2008. The moorings are labeled consecutively
93 from EG1 (inshore-most mooring) to EG7 (offshore-most mooring). Their positions are
94 shown in Figure 2, and Figure 3 details their configuration in the cross-stream plane. Details

95 about the mooring array can be found in von Appen (2012). Here we briefly summarize the
96 salient aspects of the array and the instruments used in this study.

97 [Figure 2 about here.]

98 [Figure 3 about here.]

99 Each of the moorings contained a conductivity-temperature-depth (CTD) profiler that
100 nominally sampled twice a day from 100 m to just above the bottom. The four inshore
101 moorings (EG1–4) employed Coastal Moored Profilers (CMPs) and the outer three moor-
102 ings (EG5–7) used McLane Moored Profilers (MMPs; e.g. Morrison et al., 2000). Velocity
103 was measured on the inner moorings using upward- and downward-facing acoustic Doppler
104 current profilers (ADCPs) sampling hourly, and using travel-time acoustic current meters
105 (ACMs) attached to the MMPs (measuring twice a day) on the outer moorings. As such,
106 it was planned to obtain multiple vertical sections each day of hydrographic variables and
107 velocity across the array. In addition, half hourly measurements of temperature, conductiv-
108 ity, and pressure were obtained from Microcats mounted near the ocean floor and on a 47 m
109 long wire extending buoyantly above the top floats of the moorings.

110 Complications arose from the use of steel spheres for the top floats. In particular, the
111 compasses of the ADCPs mounted on the floats were compromised by the magnetic fields
112 induced in the spheres’ steel by the Earth’s magnetic field. Fortunately, the measurement
113 range of the deep upward-facing ADCPs extended close to the depth of the top floats on the
114 inner moorings, while the ACMs also measured velocities near the top floats on the outer
115 moorings. This allowed for a direct comparison of the upper ADCP records to those of
116 the deeper instruments near a common depth. The speed comparison was very favorable,
117 while the angles differed as a function of the orientation of the flow. Using theory devel-
118 oped to correct compasses on steel ships (National Geospatial-Intelligence Agency, 2004),
119 together with the angles measured by the deeper instruments, we were able to correct the

120 compromised ADCP records to within $\approx 10^\circ$ of the current direction (see von Appen, 2012,
121 for details).

122 Unexpectedly strong currents occurred regularly during the deployment period, asso-
123 ciated with the passage of the DSOW cyclones. Velocities regularly exceeded 1 m/s over
124 large parts of the water column near the center of the eddies, while speeds of 1.5 m/s were
125 not uncommon. This resulted in mooring blowdowns that at times exceeded 500 m as de-
126 termined from the pressure sensors on the microcats. During the blowdowns the moored
127 profilers were either unable to traverse the wire (instead providing a point measurement
128 at the location where the instrument was stuck) or returned a partial profile. In addition,
129 the bottom mounted ADCPs tilted beyond the range of their tilt sensors (23°) during the
130 larger blowdown events. Although the pressure sensors on the top microcats went beyond
131 their rated range during the blowdowns, the resulting pressure records could be corrected
132 as long as the depth was less than about 520 m. Likely because of this extraordinarily ener-
133 getic environment, all of the the CMPs stopped profiling prematurely. The shortest record
134 was one month at mooring EG2, while the longest record was 8 months at mooring EG1
135 (although after the CMPs stopped profiling they returned point timeseries of temperature
136 and salinity). Consequently, it was impossible to construct vertical sections as had been
137 planned. However, the data return (particularly for the velocity) was sufficient to carry out
138 our analysis of the DSOW cyclones.

139 The tidal signal on the outer shelf and upper slope (moorings EG1–3) was significant,
140 with a combined amplitude for the constituents O_1 (25.82 h), K_1 (23.93 h), M_2 (12.42 h),
141 and S_2 (12.00 h) of up to 25% of the standard deviation of the full velocity records. These
142 tidal signals were removed from the ADCP records using a tidal fit to the data (Pawlowicz
143 et al., 2002). Tidal amplitudes at the remaining moorings were less than 0.03 m/s and
144 therefore negligible compared to the typical variability in the records. Hence, the records at
145 EG4–7 were not de-tided. After de-tiding, the velocities were rotated into an alongstream

146 and cross-stream coordinate system. All obtained velocity records were combined into a
147 single record and the alongstream direction was defined as the principle axis of variance
148 of this record (the principal axis differed by less than 10° for the different depths and
149 different locations across the array). The resulting alongstream direction of -110°T (i.e.
150 west-southwestward) also coincides with the average direction of the shelfbreak topography
151 in the study region (Figure 2). From here on, the variable x denotes alongstream distance
152 (positive equatorward), the variable y denotes cross-slope distance (positive offshore), and
153 the variable z denotes vertical distance (positive upwards).

154 *2.2. Satellite SST data*

155 Satellite sea surface temperature (SST) images are used in this study. They are Level 2
156 products of the MODIS Aqua and MODIS Terra satellites. MODIS is the Earth Observing
157 System (EOS) Moderate Resolution Imaging Spectrometer, and the processing steps for the
158 Level 2 product are documented in Brown and Minnett (1999). The spatial resolution of the
159 infrared satellite measurements at nadir is 1 km, and the Level 2 product takes advantage of
160 this full resolution without smoothing in space and time. The study region is cloud covered
161 80–90% of the time. Since infrared radiation does not penetrate clouds, consecutive images
162 are often several days apart. The Level 2 product contains a preliminary bad data detection
163 flag. This captures both possible clouds and data pixels with temperatures strongly different
164 from their surrounding pixels. Unfortunately, this tends to reject pixels near the high SST
165 gradient region of the East Greenland /Irminger Current hydrographic front (where tem-
166 peratures can range from from $0\text{--}2^\circ\text{C}$ on the shelf to $8\text{--}10^\circ\text{C}$ over the slope). Since this is a
167 region of particular interest, we devised an adjusted cloud cover rejection routine as follows.
168 Cloud tops are much colder than -2°C , the coldest reasonable ice-free SST. Hence, scattered
169 clouds result in spots of unrealistically cold satellite-measured temperatures surrounded by
170 a region of transitional temperatures where both sea-surface and cloud-top emitted infrared
171 radiation reaches the spectrometer. Therefore, areas characterized by occurrences of these

172 very cold temperatures were manually removed, leaving mostly continuous regions of tem-
173 peratures in the -2–12°C range, reasonable for ice-free SST. No further adjustments, other
174 than removal of entire regions of the domain with questionable data, were applied.

175 3. Methods

176 As discussed above, when DSOW cyclones passed the array the mooring located near
177 the cyclone center was significantly blown down (neighboring moorings were affected as well,
178 although not as severely). As such, no complete hydrographic profiles were obtained in the
179 center of the cyclones, only on the edges. Keep in mind, however, that the bottom microcats
180 recorded temperature and salinity throughout. Regarding velocity, the ADCPs mounted on
181 the top floats did record data during blowdowns, although their measurement depth was
182 deeper than the intended 0–100 m range. In addition, the downward-facing ADCP mounted
183 below the top float of mooring EG4 (bottom depth of 900 m) was functional during these
184 events. Consequently, we did obtain velocity profiles at both the center and the edges of the
185 cyclones. Fortuitously (as detailed below), the majority of the cyclones passed near mooring
186 EG4. At this location a nearly continuous (>95% of planned measurements) timeseries of
187 velocity was recorded spanning the middle portion of the water column (from 260 m to
188 660 m depth). Hence, despite the data gaps, there was enough information to provide a
189 detailed view of the velocity structure of the cyclones, with complementary hydrographic
190 information near the sides of the features as well as along the bottom.

191 [Figure 4 about here.]

192 As an example of how these cyclone passages are recorded by the mooring array, Fig-
193 ure 4 presents the velocity records obtained during the passage of a DSOW cyclone onshore
194 of mooring EG6. As the cyclone passed near EG6 (at 0930Z on October 19, 2007), the
195 cross-stream velocity changed from strongly offshore to strongly onshore (Figure 4f,h,j). At

EG6 (near the eddy center), the mooring blowdown temporarily lessened at this time (Figure 4g,h). On the onshore side, the eddy swirl velocity led to an increase in the downstream flow (Figure 4c,e) that did not extend to EG3 on the upper slope (Figure 4a). Conversely, on the offshore side, the swirl velocity of the cyclone led to a decrease in the alongstream velocity (Figure 4i).

This sequence of events was qualitatively the same for all passing cyclones. As such, we developed a methodology within the framework of a graphical user interface to identify when and where DSOW cyclones passed the mooring array. This encompassed only the moorings on the continental slope, EG3–7 (no cyclones were detected on the shelf). The timeseries in question were visually inspected in two-day segments (similar to Figure 4) and the time of passage of a given DSOW cyclone was identified as a continuous variable, while its cross-slope location was identified as a discrete variable that could take 15 distinct bin values: onshore of EG3, near EG3, offshore of EG3, onshore of EG4, near EG4, etc. The fact that the number of eddies identified within the two bounding bins (onshore of EG3 and offshore of EG7) accounts for less than 5% of all identified eddies (Figure 6 below), suggests that these discrete bins essentially bracket the locations at which DSOW cyclones pass the mooring array.

[Figure 5 about here.]

The velocity field measured by the moorings during the passage of a cyclone is schematically shown in Figure 5. Comparing this schematic to examples such as the one shown in Figure 4, the following criteria were devised for eddy detection. The first two criteria are required for the identification of a cyclone, while the remaining three criteria provide supporting information:

1. The cross-stream velocity switches from strongly offshore to strongly onshore. The time of the eddy passage corresponds to when this transition occurs at the mooring

closest to the eddy center (defined from the other criteria below).

2. The downstream (positive alongstream) velocity increases significantly. Such an increase is indicative that the mooring in question is located near or onshore of the eddy center.
3. The downstream (positive alongstream) velocity decreases at a mooring signifying that the mooring is offshore of the eddy center.
4. Mooring blowdown is a proxy for water column-integrated speed. Two successive vertical excursions of a mooring (with a partial recovery in between, e.g. Figure 4g,h) indicate that the mooring in question is near the center of the eddy, i.e. inside the radius of approximate solid body rotation where the azimuthal velocity decreases toward the center of the feature. A single vertical excursion, on the other hand, indicates that the respective mooring is near the edge of the eddy.
5. An increase and subsequent decrease in near-bottom potential density (or corresponding signature in potential temperature) at a mooring indicates the close proximity of a cyclone (i.e. the presence of DSOW). This information helped constrain both the time of passage of the cyclone as well as its cross-stream location.

Applying these criteria to the mooring data made it possible to unequivocally identify the cyclones. There were virtually no cases when only small amplitude variations in velocity consistent with the first two criteria were observed. Once the anomalies were larger than the background, they were typically strong (amplitudes larger than three times the values common in the absence of the cyclones) and also exhibited some or all of the three supporting criteria. Employing the five criteria made it possible to unambiguously assign roughly 50% of the identified eddies to a single horizontal bin. For the remaining cases, the placement into two neighboring bins was ambiguous and the final assignment to one of those bins was done subjectively, which should be considered as part of the uncertainty in the resulting locations of the eddies as determined from this procedure. Based on the distance between

the moorings (which increases from 7 km on the upper slope to 10 km in deeper water), the cross-stream locations of the cyclones are known to within 2–3 km. Based on the sampling rate of the ADCPs, the times when the cyclones passed the array are known to within 1 hour.

4. Cyclone Statistics

In the 395 days of mooring array data, 190 cyclonic eddies were identified using the method described above. A histogram of their occurrence in the cross-stream plane is shown in Figure 6 (blue bars). Because the widths of the bins change across the slope, we also show a normalized histogram (red curve) which indicates the number of eddies per 2 km of cross-slope distance observed over a year. One sees that the cross-stream distribution of the cyclones is strongly peaked approximately 10 km seaward of the shelfbreak in the vicinity of mooring EG4 at a water depth of 900 m (Figure 6). This implies that more than 60 cyclones per year pass by this location. Note that the eddy count decreases sharply in the onshore direction, consistent with the notion that there are no cyclones at or inshore of the shelfbreak. The distribution decreases less rapidly in the seaward direction, and there are still eddy occurrences 40 km offshore of the shelfbreak near mooring EG7 in 1600 m water depth. However, the shape of the distribution suggests that the population of eddies offshore of the last bin is very small. The sill depth at Denmark Strait is 650 m, hence the majority of the cyclones descend approximately 250 m over the 280 km distance to the mooring array. This corresponds to a vortex stretching of 40%, which would lead to the generation of relative vorticity of $0.4f$ (40% of the planetary vorticity) in the absence of frictional effects.

[Figure 6 about here.]

Is there temporal variability associated with this cross-stream distribution? The data indicate that while there are short-term trends, as happens for the running mean of any

272 random function, there are no apparent longer term patterns (Figure 7a). In particular, there
273 is no apparent seasonal signal. The separation time between consecutive eddies (Figure 7b)
274 ranges from near zero to 8 days, with a mean of 2.1 days, although the two extreme separation
275 times are rare. Near zero separation times occur when one cyclone passes close to the
276 shelfbreak (near EG3) while another cyclone simultaneously passes far offshore (near EG7).
277 The other extreme corresponds to extended periods with no cyclones at all during which the
278 velocity variability was weaker than during periods with cyclones. As with the cross-stream
279 distribution of the cyclones, the cyclone separation timeseries (Figure 7b) does not exhibit
280 any longer term trends and no apparent seasonality. This is notable because the atmospheric
281 forcing in this region does have a large seasonal signal, with strong winds and significant
282 buoyancy forcing in the fall and winter months (e.g. Harden et al., 2011; Moore et al., 2013).
283 This implies that the cyclones are not influenced by the atmosphere, and that the dynamics
284 of their formation and propagation are a purely oceanic phenomenon. It is also consistent
285 with the model results of Haine et al. (2009) and Spall and Price (1998), where DSOW
286 cyclones form from a steady outflow through Denmark Strait.

287 [Figure 7 about here.]

288 On average, an eddy passes by the array every other day which means that they are a
289 ubiquitous feature of the flow in this region. We note that the separation time of 2.1 days
290 is very close to the 2.3 days computed by Bruce (1995) using SST data. However, the
291 separation time in that study was calculated as the distance between consecutive eddies
292 (54 km) divided by the translational speed (0.27 m/s). As will be shown in the following
293 sections, the method employed by Bruce (1995) appears to significantly underestimate the
294 in-situ translational speed of the DSOW cyclones and, therefore, the agreement between the
295 two separation time estimates could be coincidental.

5. Composite Cyclone

As mentioned in Section 3, the only complete velocity timeseries returned by the array is in the middle water column at mooring EG4. Fortuitously, the vast majority of DSOW cyclones passed the array in the vicinity of this mooring (Figure 6). We now describe a statistical method that maps out the full three dimensional velocity structure of a composite DSOW cyclone using only velocity data from mooring EG4.

The data at EG4 capture different parts of the passing cyclones depending on the proximity of the cyclones to the mooring. For example, EG4 records the velocity on the offshore edges of eddies passing at EG3, and it records the velocity near the centers of eddies passing at EG4. If the eddies passing the different locations are statistically similar, then their mean structure can be determined in the following way. The measurements at EG4 during the 17 times when eddies passed at EG3 map out the offshore edge of the mean eddy. Likewise, the measurements at EG4 during the 33 times when eddies passed at EG4 map out the center of the mean eddy. While eddies passing at different depths are going to be somewhat different (e.g. in the degree of their stretching), for the following analysis we assume that the property variation in the cross-stream direction is small over the diameter of the eddies. An investigation of the degree of cross-stream variation (von Appen, 2012) supports this assumption, as do the results below.

We now composite the Eulerian mean structure of DSOW cyclones in the vicinity of mooring EG4 starting with the depth-mean velocity field between 260 m and 660 m, where the velocity measurements are complete. Later in the paper (Subsection 5.5) we examine the vertical structure of the typical cyclone. Although one may wonder how representative this composite eddy is, our data are unfortunately not able to objectively quantify this. We note, however, that the velocity expressions of many of the cyclones as seen in the graphical user interface were qualitatively and quantitatively similar. This implies that the scales of the composite cyclone as described here are in fact representative of a significant number of

the individual cyclones that passed the mooring array.

5.1. Depth-mean background velocity

Figure 8 shows the depth-mean velocity field between 260 m and 660 m in a top-down view, with the center of the cyclone located at $(x = 0, y = 0)$. The observer is situated on the East Greenland shelf looking offshore, so that the mean flow and the cyclone translation are towards the right. Bins in the cross-stream direction are averages from all the eddies that passed at that particular offset from EG4. The temporal offset with respect to the time when the eddy passed the mooring array is indicated along the top of the plot with negative values corresponding to times preceding the arrival of the eddy center. We used the propagation velocity of the eddy (which we define and derive below) to transform the temporal measurements into alongstream distance, plotted along the bottom of the horizontal axis. Color indicates the depth-mean speed in each bin and the black lines indicate the vector velocity. The white line near -11 km corresponds to the approximate location of the shelfbreak in this transformed coordinate system.

[Figure 8 about here.]

We now decompose the full velocity field (u, v) as a function of alongstream and cross-stream location into the following components, plus a residual encompassing noise as well as components that we cannot determine from the available data.

$$u(x, y) = u_b + u_c(x) - v_a(r) \sin(\theta) + \text{residual} \quad (1)$$

$$v(x, y) = v_b + v_a(r) \cos(\theta) + \text{residual} \quad (2)$$

Here $r = \sqrt{x^2 + y^2}$ is the radius from the center and $\theta = \arctan(\frac{y}{x})$ is the azimuthal angle measured counterclockwise with 0° being in the direction of the mean flow. The first component is the background mean flow that is also present in the absence of DSOW

cyclones. The available data allow us to estimate the background velocity (u_b, v_b) whose
 alongstream and cross-stream components are uniform in space. The next component is the
 velocity with which the cyclone self-propagates. As the cyclone propagates along the East
 Greenland slope, it induces a velocity in the ambient fluid (including in the wake of the
 cyclone). These two velocity components have alongstream and cross-stream structure, but
 with the available data we are only able to determine the alongstream structure of the sum
 of these two components. We call this sum, which includes the translation of the cyclone
 and the induced velocity in the ambient water, the “co-translational” velocity $u_c(x)$. This
 means that the cross-stream component and structure of the co-translational velocity field
 is contained in the residual which we cannot determine from the available data. We note
 that this co-translational velocity is the Eulerian velocity measured by the moorings as the
 cyclones pass the array. It will be weak far away from the cyclones where the influence of
 the features is weak. The co-translational velocity $u_c(x)$ is also different from the spatially
 uniform propagation velocity of the frame of reference in which the cyclone dynamics can
 be evaluated. The frame of reference propagates with the total velocity at the exact center
 of the eddy (see Lilly and Rhines, 2002) which in our notation is $u_b + u_c(x = 0)$. Finally, we
 determine the azimuthal velocity $v_a(r)$. All of the above velocity components are depth-mean
 quantities.

There is significant flow in the absence of cyclones, associated with the East Green-
 land/Irminger Current, the spill jet, and the DWBC. The influence of a DSOW cyclone
 persists for less than 18 hours before and after its center passage (Figure 8). Roughly
 140 days (35% of the velocity record) are more than 18 hours away from the center of a
 cyclone passing the mooring array. The depth-mean background flow in the alongstream
 direction during those 140 days is $u_b = 0.27$ m/s equatorward and $v_b = 0.04$ m/s directed
 offshore (Figure 8b). Given the angular uncertainty in the current direction (compare the
 definition of the alongstream direction), this offshore velocity is not meaningfully different

from zero.

5.2. Depth-mean flow associated with the translation of the composite cyclone

[Figure 9 about here.]

Subtracting (u_b, v_b) from the full flow field reveals the velocity structure of the eddy with respect to the background flow (Figure 9). Away from the feature there is very weak flow with essentially no structure. On the onshore side of the cyclone (negative cross-stream distance), the positive co-translational velocity and the positive azimuthal velocity superpose resulting in strong downstream velocity. On the offshore side, the positive co-translational velocity and the negative azimuthal velocity result in weak downstream flow. Along the center slice of the cyclone ($y = 0$), the alongstream flow is due only to the translation of the fluid with the cyclone and to the motion that is induced in the ambient fluid that is affected by the passing cyclone. In particular, the azimuthal velocity of the eddy does not contribute to the co-translational velocity $u_c(x)$ along $y = 0$. The same is true for the cross-stream average over an area that is symmetric around $y = 0$. In order to decrease the noise in the estimate of $u_c(x)$, we averaged the velocities in each bin between $y = -6$ km and $y = 6$ km at each alongstream location to obtain the profile of the co-translational velocity (Figure 9b).

The co-translational velocity increases from approximately zero before the cyclone, reaching a maximum of 0.45 m/s about 2.5 km after of the center of the cyclone, and decreases thereafter (but not back to zero). We assume that this maximum value approximately corresponds to the translational velocity u_t of the cyclone with respect to the background flow. This is consistent with the model of an isolated self-advecting eddy that could be envisioned as a vertical cylinder being dragged through a fluid. The alongstream flow is due to the translation of the circularly symmetric feature and to the induced motion in the ambient fluid. This induced motion has a component that is symmetric before and after the translating feature and also contains the wake, which is only present on the trailing side. Due to

the velocity in the wake, the alongstream velocities behind the cyclone are stronger than in front of it. Since DSOW cyclones are not characterized by step discontinuities in properties (as a dragged cylinder would be), the co-translational velocity ramps up to and down from its center value in a smooth fashion, as seen in Figure 9. The derivation of the precise detailed structure of $u_c(x)$ for a baroclinic Gaussian eddy on a topographic β -plane with stratification is complicated and beyond the scope of the present work. We note, however, that the qualitative elements of $u_c(x)$ deduced here correspond to the expected structure: near-zero velocity far from the cyclone, nearly constant translational velocity in the small (approximate solid body) core of the cyclone, and a smooth ramp up/down of the induced motion in the domain of influence of the cyclone in the ambient fluid.

Self-advection of a DSOW cyclone is consistent with the propagation of a finite amplitude, non-linear topographic Rossby wave. The restoring force for a topographic Rossby wave is associated with the change in potential vorticity experienced as the vortex column migrates into deeper or shallower water. For long waves, the linear topographic Rossby wave speed is (Pedlosky, 2003):

$$c = -\beta R_d^2 = \frac{f}{H_0} \frac{dH}{dy} R_d^2, \quad (3)$$

where R_d is the internal Rossby radius, $\beta = \frac{-f}{H_0} \frac{dH}{dy}$ is topographic β , f is the Coriolis parameter, and H_0 is the mean water depth of the isobath along which the topographic Rossby wave propagates. To estimate this speed, we take H_0 (here considered as a positive quantity) as the bottom depth of EG4 (900 m), and approximate the bottom slope as the difference in water depth between EG3 and EG5 (650 m) divided by their separation (14 km). The stratification N in the middle water column is $2.2 \times 10^{-3} \text{ s}^{-1}$ (Figure 13c below). Different estimates for the Rossby radius are common: $R_d = \frac{NH}{f}$ and $R_d = \frac{NH}{\pi f}$, leading to a range of 5–15 km at 900 m. The approximate radius of the cyclones of 8 km (Subsection 5.3 below) is within this range. Taking R_d to be 8 km results in a topographic Rossby wave speed

418 of 0.44 m/s, very similar to our observational estimate of the self-advection velocity with
 419 respect to the background flow u_t (0.45 m/s). We note that there is significant uncertainty
 420 in this estimate due to the wide range in and the squared dependence on the Rossby radius,
 421 and there will be a correction factor due to the difference between linear wave dynamics and
 422 the finite amplitude vortex dynamics of the DSOW cyclones. Another way to predict the
 423 propagation velocity is $c = \frac{g'}{f} \frac{dH}{dy}$ as proposed by Nof (1983) where g' is the reduced gravity
 424 $\frac{\Delta\rho}{\rho_0} g$. The density anomaly $\Delta\rho$ is not well-defined for our continuous stratification situation.
 425 However, assuming reasonable values ($\approx 0.1 \text{ kg/m}^3$) for the density anomaly results in the
 426 same order of magnitude for the propagation speed. As such, the good agreement between
 427 the predicted and observed value of u_t suggests that the restoring force associated with the
 428 deflection of a vortex column can account for the observed self-advection.

429 The sum of the translational velocity with respect to the mean flow u_t and the background
 430 mean velocity u_b is the speed of the cyclone with respect to the bottom. It reaches a
 431 maximum of 0.72 m/s (Figure 9b). The sum of the background velocity u_b and the co-
 432 translational velocity $u_c(x)$ is the speed of a fluid parcel with respect to the bottom and this
 433 is the speed that was used earlier to transform the time axis into alongstream distance.

434 5.3. Depth-mean azimuthal flow of the composite cyclone

435 [Figure 10 about here.]

436 Next we remove both the background mean flow and the co-translational velocity to
 437 reveal the cyclonic flow of the isolated eddy (Figure 10). One sees that there is no flow at
 438 the center and that it increases and then decreases with radius. The concentric circles shown
 439 in Figure 10a are for visual guidance. It is clear that the majority of the flow is tangential
 440 to these circles as expected for an azimuthal flow.

441 [Figure 11 about here.]

442 Plotted as a function of radius, the binned azimuthal velocities nicely reveal the structure
 443 of the composite eddy (Figure 11a). While there is obvious scatter, a smoothed 1 km running
 444 mean of the azimuthal velocities shows a very clear signal. Starting from zero, the azimuthal
 445 speed increases nearly linearly, reaches a maximum near 6 km and then decreases smoothly
 446 to near zero around 25–30 km. The most common model for a vortex is a simple Rankine
 447 vortex which exhibits azimuthal speed proportional to radius up to a distance and then
 448 inversely proportional to radius (and results from an isolated step discontinuity in potential
 449 vorticity which is a good theoretical model, but is not expected to occur in reality). A
 450 Rankine vortex fits the linear increase due to solid body rotation near the center, but is not
 451 a good model farther out as it does not decrease quickly enough compared with the data in
 452 Figure 11a. In contrast, a Gaussian eddy (which results from a smooth PV anomaly) is an
 453 excellent model (Figure 11a). The structure of a Gaussian eddy is given by:

$$v_a(r) = v_0 \frac{r}{R_0} e^{\frac{1}{2} \left(1 - \left(\frac{r}{R_0} \right)^2 \right)}. \quad (4)$$

454 The azimuthal velocity increases nearly linearly up to a radius R_0 where it smoothly reaches
 455 its maximum velocity v_0 . Beyond this radius the velocity decreases proportional to e^{-r^2} .
 456 Unlike the Rankine vortex, the influence of the Gaussian eddy is well bounded. The fit shown
 457 in Figure 11a gives an eddy radius of $R_0 = 7.8$ km and a peak azimuthal depth-mean velocity
 458 of $v_0 = 0.22$ m/s. We also note that the average profile in Figure 11a cannot be explained
 459 as the composite of many Rankine vortices with randomly varying parameters (R_0 and v_0).
 460 Such a composite of Rankine vortices may have a similar shape to the data distribution near
 461 R_0 , but, at radii $> 1.5R_0$, the velocity only decreases as $\frac{1}{r}$. This is in contrast to the much
 462 steeper decay of e^{-r^2} (Gaussian eddy) seen in Figure 11a. This velocity fit is used below
 463 (Subsection 5.6) to infer the pressure field associated with DSOW cyclones.

464 The Rossby number $\epsilon = \frac{v_0}{f \cdot R_0}$ for these fitted parameters at $r = R_0$ is ≈ 0.22 , which
 465 indicates that, in the mean, these eddies are nearly geostrophic, but ageostrophic effects
 466 are important. It should also be noted that the descent from 650 m at the Denmark Strait
 467 sill to 900 m at mooring EG4 leads to a vortex stretching of 250 m or $\approx 40\%$. If the flow
 468 is barotropic, in the absence of friction this predicts a relative vorticity of $\zeta = 0.4f$ and a
 469 Rossby number $\epsilon = \frac{\zeta}{f}$ of 0.4. Considering that the flow is not strictly barotropic and that
 470 frictional effects lead to some loss of relative vorticity, the observed cyclones are consistent
 471 with having been generated by vortex stretching. The depth-mean azimuthal velocity fit is
 472 also shown in Figure 10b.

473 The estimates of the translational velocity $u_b + u_t = 0.72$ m/s and the radius of the cyclones
 474 $R_0 = 7.8$ km given above depend on our velocity decomposition as defined in Equations (1)
 475 and (2). They differ significantly from the previous estimates of these quantities presented
 476 by Bruce (1995), 0.27 m/s and 17 km, respectively, based on sea surface temperature data.
 477 Possible explanations for this difference are discussed in Section 6 below. We now present
 478 a separate argument which does not rely on the velocity decomposition to support the
 479 notion that DSOW cyclones are comparatively small and fast. It is assumed that the eddies
 480 are approximately circular and not, for example, elongated in the alongstream direction.
 481 The radius of maximum azimuthal velocity is where a mooring experiences its greatest
 482 blowdown. As seen in the example of Figure 4, the passage of a cyclone over a mooring
 483 leads to a double-dip blowdown in the timeseries data. If the mooring was near the radius of
 484 maximum azimuthal velocity, this double-dip would not be pronounced as the intermediate
 485 recovery would be very short compared to the hourly measurement interval. Only during a
 486 very small number of cyclones was a distinct and well-defined double-dip observed at more
 487 than one mooring. This suggests that the diameter of most cyclones is somewhat smaller
 488 than about twice the average cross-stream mooring spacing of 8 km. Hence their radius
 489 of maximum velocity is somewhat smaller than 8 km as determined from the ADCP and

490 pressure sensor data on all moorings and consistent with the above estimate of $R_0=7.8$ km.
 491 The typical scale of 5–8 km for the radius of maximum azimuthal velocity can also be seen
 492 in Figures 8a and 9 where the maximum velocities during the cyclone center passage ($t=0$)
 493 is found at a cross-stream distance of 5–8 km.

494 The passage of the radius of maximum azimuthal velocity at 0 km cross-stream distance
 495 happens roughly $t_0=3$ hours before and after the cyclone center (see the temporal axis on
 496 top of Figure 10a). The majority of the eddy influence falls within twice that radius and
 497 about ± 6 hours (Figures 9a and 8a). This leads to a propagation speed of approximately
 498 $\frac{4R_0}{4t_0}=0.72$ m/s in very good agreement with our other estimate.

499 After removing the background flow, the co-translational velocity, and the azimuthal
 500 velocity of the cyclone, the residual velocities (not shown) are weak (less than 0.1 m/s). This
 501 demonstrates that we have successfully decomposed the depth-mean velocity field associated
 502 with DSOW cyclones into the components shown in Figure 10b. Interestingly, there is
 503 an indication for increased offshore flow in the region onshore and in front of the cyclone
 504 (Figure 10a). This is consistent with “Type II” spilling as described by Magaldi et al. (2011)
 505 where such DSOW cyclones draw dense fluid off the shelf that feeds the spill jet (and hence
 506 does not return on the trailing edge of the cyclone). We note, however, that the magnitude
 507 of this signal is fairly weak compared to the noise level of our method.

508 *5.4. Bottom density associated with the composite cyclone*

509 [Figure 12 about here.]

510 Mooring EG4 was also equipped with a microcat that measured temperature and salinity
 511 near the bottom. Within a radius of about 5 km the bottom potential density (referenced
 512 to the surface) exceeds 27.8 kg/m^3 in the composite cyclone (Figure 12). This indicates the
 513 presence of DSOW (as defined by Dickson and Brown (1994)) in the core of the cyclones.
 514 When plotted as a function of radius (Figure 11b), the bottom density anomaly displays a

515 clear signature that is well approximated by the Gaussian fit

$$\sigma'_e(r) = \sigma_0 e^{-\frac{1}{2}\left(\frac{r}{R_0}\right)^2}, \quad (5)$$

516 where the radius $R_0 = 7.8$ km is the same as for the Gaussian eddy velocity fit of Equation (4)
517 and the maximum density anomaly at the origin is $\sigma_0 = 0.073$ kg/m³.

518 It is important to note that while overflow water is present at 900 m bottom depth (depth
519 of EG4) when the cyclone passes, water this dense is only found deeper than ≈ 1100 m in the
520 background field. We argue that there is dense fluid inside the cyclone that is propagating
521 at the same speed as the cyclone, and that there is a dynamic link between the azimuthal
522 flow field and the density anomaly. This is different than what would be expected for the
523 passage of a linear topographic Rossby wave. Note that the passage of both a linear wave
524 and a cyclone starts with offshore directed velocities. In the former case this would bring
525 lighter fluid from higher up on the continental slope to the depth of EG4, though we note
526 that this argument would only hold exactly if density was a passive tracer. On the trailing
527 edge, the onshore velocities would advect denser fluid up to the depth of EG4. That means
528 that the decrease in near-bottom density expected from a wave is inconsistent with the
529 observed increase in density in the center of the composite cyclone. However, for dense
530 fluid to be kinematically trapped and advected by the cyclonic velocity field, the maximum
531 azimuthal velocity must be greater than the translational velocity (e.g. Flierl, 1981). This is
532 not the case for our observed peak azimuthal velocity of 0.22 m/s and translational velocity
533 of 0.45 m/s. Therefore, the dense water anomaly and the cyclonic swirl velocity have to
534 be dynamically linked resulting in their simultaneous propagation at this swift speed. A
535 detailed analysis of the dynamics associated with the composite eddy is beyond our current
536 scope. However, we note that the theoretical model of Swaters and Flierl (1991) and Poulin
537 and Swaters (1999) predicts a flow structure similar to our observations and, as such, is a

538 good model to explain the dynamics of fully developed DSOW cyclones.

539 5.5. Vertical structure of the composite cyclone

540 We now investigate the vertical structure of the composite cyclone, although recall that
541 the velocity data above 260 m and below 660 m are more sparse, and, as such, the results
542 are not as robust in these two regions.

543 [Figure 13 about here.]

544 The background flow $u_b + u'_b(z)$ increases with depth. For simplicity we assume a simple
545 linear fit where constrained by data, and a constant extrapolation elsewhere (Figure 13a).
546 This gives a velocity of 0.36 m/s at 900 m near the bottom (our observations do not extend
547 into the bottom boundary layer). Subtracting this depth-dependent background velocity
548 reveals the vertical structure of the composite eddy (Figure 14). It can again be seen that
549 the peak in the downstream velocity is behind the center, which is due to the velocity in the
550 wake of the cyclone. The cross-stream velocity is roughly symmetric about the eddy center.
551 To further quantify the vertical structure of the cross-stream velocity, a Gaussian eddy was
552 fit to the azimuthal velocity component for each 10 m depth bin in the same way that it was
553 done for the depth-mean structure (see Figure 11a). While there was little variation (less
554 than 0.5 km) in the fitted radius R_0 from top to bottom, there was a substantial difference
555 in the amplitude v_0 . Therefore, the same calculation was repeated, but with the radius fixed
556 to the depth-mean value of $R_0 = 7.8$ km. The resulting amplitudes of the azimuthal velocity
557 are shown in Figure 13b. The vertical structure is well-represented by a quadratic fit with
558 zero velocity at the bottom and zero vertical shear at the top. This implies that the DSOW
559 cyclones at this location on the slope are surface-intensified, with a maximum azimuthal
560 velocity of 0.34 m/s near the surface.

561 [Figure 14 about here.]

[Figure 15 about here.]

As noted earlier, the moored profilers measuring the hydrographic properties were not able to complete full-depth profiles in the presence of the large velocities inside of the DSOW cyclones. However, on the offshore side of the cyclones, the upstream directed azimuthal velocity leads to a relatively weak total velocity (Figure 8) and the profilers did perform comparatively well there. This allows us to use data from mooring EG5 to construct a composite of the density field approximately 7–10 km seaward of the cyclone center (Figure 15). Along this slice the density strongly increases near the bottom. From a Eulerian point of view, one sees that the waters denser than $\approx 27.7 \text{ kg/m}^3$ are raised by more than 200 m during the passage of the cyclones compared to the ambient conditions. In contrast, the depths of the overlying isopycnals are only weakly affected, and this leads to a significant increase of the stratification in the middle of the water column (around 600 m depth). The downstream velocity in the lower part of the water column where the density anomaly is large is faster than in the upper part (Figure 14a). This means that the dense fluid is advected faster than the overlying water with the ambient density structure. Figures 14 and 15 demonstrate that the density anomaly associated with DSOW cyclones is swiftly advected in the lower part of the water column while the azimuthal velocity is strongest in the upper part of the water column. This is very much in line with the laboratory and numerical results of Whitehead et al. (1990) and the theory of Swaters and Flierl (1991) wherein a propagating lens of dense water near the bottom is associated with an overlying cyclonic vortex.

5.6. Constructed pressure and density fields of the composite cyclone

The density field of a DSOW cyclone is of interest both to determine its equatorward transport of dense water as well as to infer its sea surface signature. As such, we now apply an indirect method, using the pressure field, to estimate the density field. The EG4 data used are the ADCP measurements of velocity, microcat measurements of bottom density,

587 and, outside of the cyclones, the moored profiler measurements of density (which are limited
588 to 150–650 m). To reduce the noise we apply fits to each of these quantities. The resulting
589 mean background density profile is shown in Figure 13c. We applied two piecewise linear fits
590 to the profile (the top 200 m, where the fit is poor, has little bearing on the result below).

591 [Figure 16 about here.]

592 To construct the pressure field we first simplify the radial momentum equation in the
593 frame of reference moving with the cyclone by neglecting friction, time-dependence, and
594 any non-linear terms not associated with the cyclostrophic balance. This also neglects any
595 asymmetries between the onshore and offshore sides of the eddy introduced by the moving
596 frame of reference used here. To leading order the following analysis holds, but we note that
597 the neglected terms may result in quantitative differences. The dynamic pressure can be
598 determined from the integral of the geostrophic and the cyclostrophic terms in the simplified
599 radial momentum equation

$$p'(r) = \rho_0 \int_{-\infty}^r \left(f v(r') + \frac{v^2(r')}{r'} \right) dr', \quad (6)$$

600 with the boundary condition that the pressure anomaly vanishes far outside of the cyclone.
601 This boundary condition is equivalent to the “Stern integral constraint” (Mory, 1985) and
602 allows the cyclone to be balanced independently of far-field interactions. Hence we need to
603 know the azimuthal velocity as a function of radius and depth, which is obtained from the
604 fits in Figures 11a and 13b, and shown in Figure 16a. We then perform the integration in
605 Equation (6) at each depth to obtain the dynamic pressure field which is shown in Figure 16b.
606 A maximum dynamic pressure anomaly of -700 Pa is achieved at the surface in the center
607 of the cyclone. This corresponds to a sea surface height depression of about 7 cm, which
608 compares well with the median SSH depression of 6 cm in the numerical model of Käse et al.
609 (2003).

Next we use the hydrostatic equation to obtain the density anomaly:

$$\rho'(z) = -\frac{1}{g} \frac{\partial p'}{\partial z}. \quad (7)$$

This density anomaly field is shown in Figure 16c. Its radial structure at the bottom is shown in Figure 16d compared to that measured by the microcat. The two curves have the same Gaussian structure with a radius of 7.8 km. The only difference is that the amplitude of the density anomaly computed from the dynamic pressure is roughly 1.8 times larger than that measured by the microcat. We note, however, that both of these estimation methods are uncertain ($\approx 20\%$ each). Additionally, Equation (6) neglects several terms in the momentum balance. At 13–15 m above the bottom, the microcat may also be located in the $O(10\text{--}100\text{ m})$ thick bottom boundary layer where enhanced mixing could lead to a weaker $\frac{\partial \rho}{\partial r}$ than in the fluid above. Additionally, we do not take into consideration the large (factor of 2–3) change in total water depth between the onshore side and the offshore side of an eddy. In light of these considerations, we suspect that the true bottom density anomaly lies somewhere between the two estimates in Figure 16d. Therefore, we take the two estimates as upper and lower bounds and present the respective full density fields.

If we add the density anomaly field obtained from the pressure gradient calculation to the full density profile outside of the cyclones (Figure 13c), we obtain the full density field shown in Figure 16e. If we divide the density anomaly field (Figure 16c) by 1.8 (the ratio between the two anomalies in Figure 16d) and add that to the density profile outside of the cyclones, we obtain the full density field in Figure 16f. Note the good qualitative agreement between these two inferred density fields and the (independent) measurements on the seaward side of the cyclones (Figure 15). From Figures 16e,f we conclude that the 27.8 isopycnal extends 60–300 m above the bottom and is confined inside a radius of 4–10 km around the cyclone center. This again compares well with the 250 m median plume thickness found by Käse

et al. (2003). The total volume of water denser than 27.8 in a typical DSOW cyclone at the 900 m isobath is thus estimated to be 2–45 km³.

We note that the center of the composite cyclone is at a water depth where the densest ambient water is typically 27.74, which is more than 0.06 kg/m³ lighter than the traditional DSOW definition of 27.8. Therefore, it might be more appropriate to consider the water coming from the overflow as that comprising the density classes which are otherwise absent at this depth. The 27.74 isopycnal is inside of a radius of about 20 km and rises about 300–370 m above the bottom (Figures 16e,f). Therefore a typical DSOW cyclone contains 130–200 km³ of water denser than 27.74.

If we divide the volume of overflow water inside a typical DSOW cyclone by the period over which the cyclones pass the mooring array (2 days), we obtain the volume transport of plume water due to the cyclones. Using the typical definition of overflow water (27.8), we obtain a transport of 0.01–0.26 Sv. Using the broader definition (27.74), we obtain a transport of 0.7–1.2 Sv. Compared to a total overflow water (>27.8) transport of 5.2 Sv in this region (Dickson and Brown, 1994), these values are rather small. However, this is due to the fact that the cyclones are so high up on the slope (at EG4 in 900 m) and hence do not contain much DSOW. Since the background density at greater depth is already larger than the overflow water density criterion, cyclones in deeper water contain disproportionately more overflow water than cyclones around 900 m depth. Even though their number is small (Figure 6), the overflow transport estimate would increase significantly if we could include the exact dimensions of these deeper eddies in our estimates.

6. Investigating the Sea Surface Temperature Signature of DSOW Cyclones

The sea surface temperature along the East Greenland slope is dominated by the contrast between cold (≈ 0 – 4°C) polar-origin water on the shelf and warm (≈ 8 – 12°C) subtropical-origin water in the Irminger basin. This water mass front is associated with the surface-

intensified East Greenland/Irminger Current. The 6°C SST isotherm is a good proxy for the frontal location. Using the 63 partially cloud-free SST images obtained between September 2007 and October 2008, we produced a map of the frontal locations in the vicinity of the mooring array (Figure 17). It can be seen that the front meanders substantially. Its mean location roughly tracks the 500 m isobath (slightly deeper than the shelfbreak), and the standard deviation is about 10 km. The mooring array brackets the frontal location to within ± 1 standard deviation. The median location of the DSOW cyclones passing by the mooring array is a few kilometers offshore of the mean location of the 6°C isotherm.

[Figure 17 about here.]

The approximate co-location of the SST front and the path of DSOW cyclones means that the surface velocity field of the cyclones is generally in close vicinity to the SST front and will likely impact the front. Disturbances in SST and anomalies in DSOW transport associated with DSOW cyclones were seen to move along the East Greenland slope together for six days in the numerical model of Magaldi et al. (2011). The premise that SST disturbances and DSOW cyclones move together was also used by Bruce (1995) to track cyclones. The 33 SST disturbances identified by Bruce (1995) along the ≈ 700 km of the East Greenland shelfbreak were found to progress equatorward at 0.27 m/s with a standard deviation of 0.11 m/s. This was subsequently interpreted as the typical propagation velocity of DSOW cyclones along the East Greenland slope. As shown above (Subsection 5.2), our in-situ measurements suggest a typical translational velocity with respect to the bottom of 0.72 m/s. We now examine possible reasons for this large discrepancy.

[Figure 18 about here.]

One simple hypothesis would be that there is significant interannual variability in DSOW cyclone properties and that during 2007–08 they translated faster than during 1987–90 (the

time period analyzed by Bruce (1995)). In order to address this hypothesis, we repeated the methodology of Bruce (1995) for all SST images between September 2007 and October 2008 that were at least partially cloud-free. Along the first 250 km of the East Greenland shelfbreak, this revealed several spiral or hook-like features on the SST front qualitatively and quantitatively similar to the ones shown in Figure 2 of Bruce (1995). Over this year-long period, 58 SST disturbances could be identified in more than one SST image, and their tracks are shown in Figure 18. Note that the number of SST disturbances at the mooring array location is very small (roughly five) and a statistically meaningful comparison between individual features in SST and the mooring record is thus not possible. Of the 58 disturbances, 40 were trackable in the sense that they were identified in SST images more than 6 hours apart. Their propagation speed was 0.37 m/s with a standard deviation of 0.17 m/s. This is slightly faster than the mean of Bruce (1995), but the two estimates agree within their standard deviations. Hence interannual variability cannot by itself explain the observed difference.

Both the topographic Rossby wave speed and the Nof speed are proportional to the bottom slope. As such, a second hypothesis to explain the discrepancy between our results and those of Bruce (1995) is that the bottom slope at the mooring array is steeper than elsewhere, thereby accounting for the faster propagation speeds determined from the mooring array data. We analyzed the General Bathymetric Chart of the Oceans (GEBCO) at 30 arc second resolution to determine the bottom slope near the 900 m isobath. West of 35°W the slope becomes much steeper (Figure 1). However, the bottom slope within 100 km of the mooring array where we tracked the SST disturbances (Figure 18) varies by only about $\pm 50\%$ of the value at the array site. Based on this simple argument, one might expect that, compared with the value at the mooring array location, the propagation speed along the East Greenland slope is both faster in some places and slower in other places with a mean not greatly different from the value at the mooring array location. The varying bottom slope

708 can therefore also not fully explain the difference in the observed speeds.

709 We propose a third hypothesis to explain the difference between the DSOW cyclone in-
710 situ translational velocity and the propagation speed of the SST disturbances; in particular,
711 that the SST disturbances are not propagating with the DSOW cyclones. In this scenario
712 the SST disturbances could be initially generated by some process (e.g. DSOW cyclones just
713 downstream of the sill or baroclinic instability of the EGC/IC front) and then propagate
714 independently of the deep DSOW cyclones along the East Greenland slope. Lozier et al.
715 (2002) studied the propagation speed associated with meanders of the Mid-Atlantic Bight
716 shelfbreak front. They found that the meanders propagate at a velocity slower than or equal
717 to the mean surface speed of the frontal jet. Their situation is similar to the EGC/IC front
718 suggesting that once the SST disturbances are generated, their speed will not exceed the
719 mean surface velocities. Using the mooring data from the present array, in the absence of cy-
720 clones, von Appen (2012) found the near-surface EGC/IC frontal jet speed to be ≈ 0.25 m/s,
721 which is in line with the speed of the SST disturbances calculated above and by Bruce (1995).
722 In the model of Swaters and Flierl (1991) and in our mooring observations (Section 5), the
723 azimuthal velocity field of the cyclone cannot kinematically trap fluid and only the dense
724 water in the lower part of the eddy moves at the fast propagation speed. Nonetheless, there
725 may be times during the evolution of DSOW cyclones when the peak azimuthal velocity
726 $v_0(z = 0)$ is greater than the propagation speed u_t . For $u_t/v_0 < 1$ kinematic trapping would
727 occur (Flierl, 1981). For the duration of such kinematic trapping, the cyclones could form
728 spiral and hook like features in the SST field. As the cyclones evolve, the ratio u_t/v_0 might
729 decrease to values below one (at the mooring array location it is ≈ 0.76). At this point the
730 cyclones would no longer trap the fluid near the sea surface leaving the SST disturbances
731 they generated behind to propagate with the mean surface speed. While this scenario is
732 consistent with previous studies on DSOW cyclones and the observations presented here,
733 future investigations are required to test its validity.

7. Summary

Using data from a cross-shelfbreak mooring array 280 km downstream of Denmark Strait, we identified 190 DSOW cyclones. On average, an eddy passed the array every other day, most of them near the 900 m isobath. The composite velocity field of a DSOW cyclone in the middle water column (260–660 m) shows that the features typically propagate at 0.47 m/s with respect to the mean flow, which is consistent with the propagation of a topographic Rossby wave and the Nof speed. Their propagation velocity with respect to the bottom is 0.72 m/s, and they have a peak depth-mean azimuthal velocity of 0.22 m/s at a radius of 7.8 km. These values are substantially different from the statistics presented by Bruce (1995) and the 25–35 km distance between consecutive eddies seen in the numerical model of Spall and Price (1998). We propose a scenario in which the SST disturbances tracked by Bruce (1995) would propagate with the mean flow of the East Greenland/Irminger Current rather than with the DSOW cyclones underneath. This could be an explanation for the differences between the results of Bruce (1995) and our study as contrasted in Table 1.

[Table 1 about here.]

We have shown the DSOW cyclones to be energetic contributors to the variability several hundred kilometers downstream of Denmark Strait. However, such variability is not observed farther south along the East Greenland slope in the vicinity of Cape Farewell (e.g. Bacon and Saunders, 2010; Daniault et al., 2011). This implies that the cyclones decay, but the mechanisms by which this happens and the distance over which this occurs remain to be investigated.

Acknowledgments

The authors wish to thank Paula Fratantoni, Frank Bahr, and Dan Torres for processing the mooring data. The mooring array was capably deployed by the crew of the *R/V Árni*

Friðriksson and recovered by the crew of the *R/V Knorr*. We thank Héðinn Valdimarsson for his assistance in the field work. We are grateful for helpful discussions with Paola Rizzoli, Mike Spall, and Amy Bower. Three anonymous reviewers provided valuable suggestions. Creation of the MODIS satellite data sets is credited to the NASA Ocean Biology Processing Group (OBPG), the NASA Jet Propulsion Laboratory (JPL), and the University of Miami Rosenstiel School of Marine and Atmospheric Science (RSMAS). Funding for the study was provided by National Science Foundation Grant OCE-0726640 and the Arctic Research Initiative of the Woods Hole Oceanographic Institution.

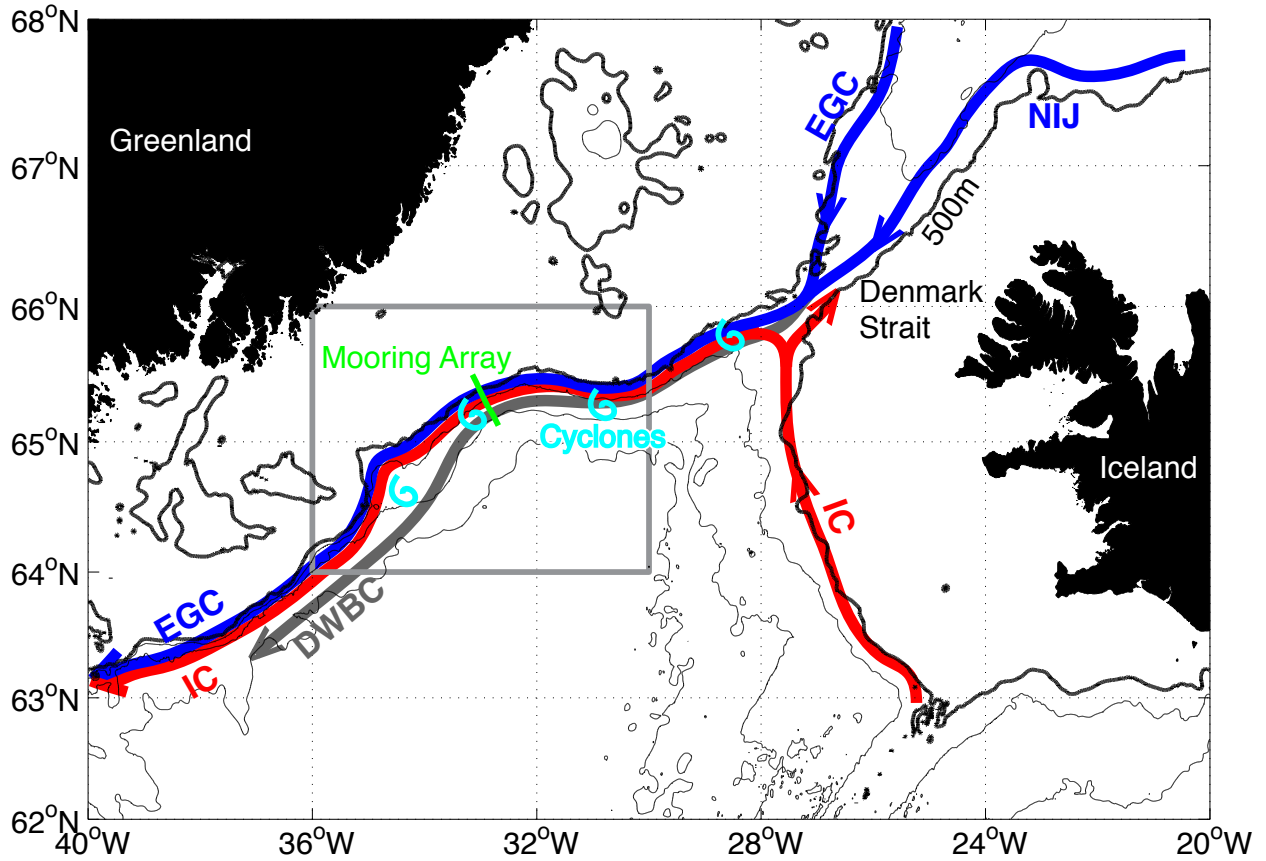

Figure 1: Map of the study region. The location of the mooring array as well as the approximate region populated by DSOW cyclones is shown along with some of the important currents in the region: Irminger Current (IC), East Greenland Current (EGC), North Icelandic Jet (NIJ), and Deep Western Boundary Current (DWBC). South of Denmark Strait, along the East Greenland shelfbreak, the EGC and IC flow together as a single jet referred to in the text as the East Greenland/Irminger Current.

Figure 2: Vicinity of the mooring array with the along-stream direction and the depth-mean background velocity of 0.27 m/s. Bathymetric data are from the General Bathymetric Chart of the Oceans at 30 arc second resolution.

Figure 3: Cross-sectional view of the East Greenland mooring array. The different instruments and their sampling schedules are explained in the legend. The nominal depth range sampled by the CMPs and MMPs is shown in red. The bottom depth along the mooring line, measured by the ship's echo sounder, is shown in black. The acronyms are as follows: CMP: Coastal Moored Profiler, ACM: Acoustic Current Meter, MMP: McLane Moored Profiler, ADCP: Acoustic Doppler Current Profiler, MC: Microcat.

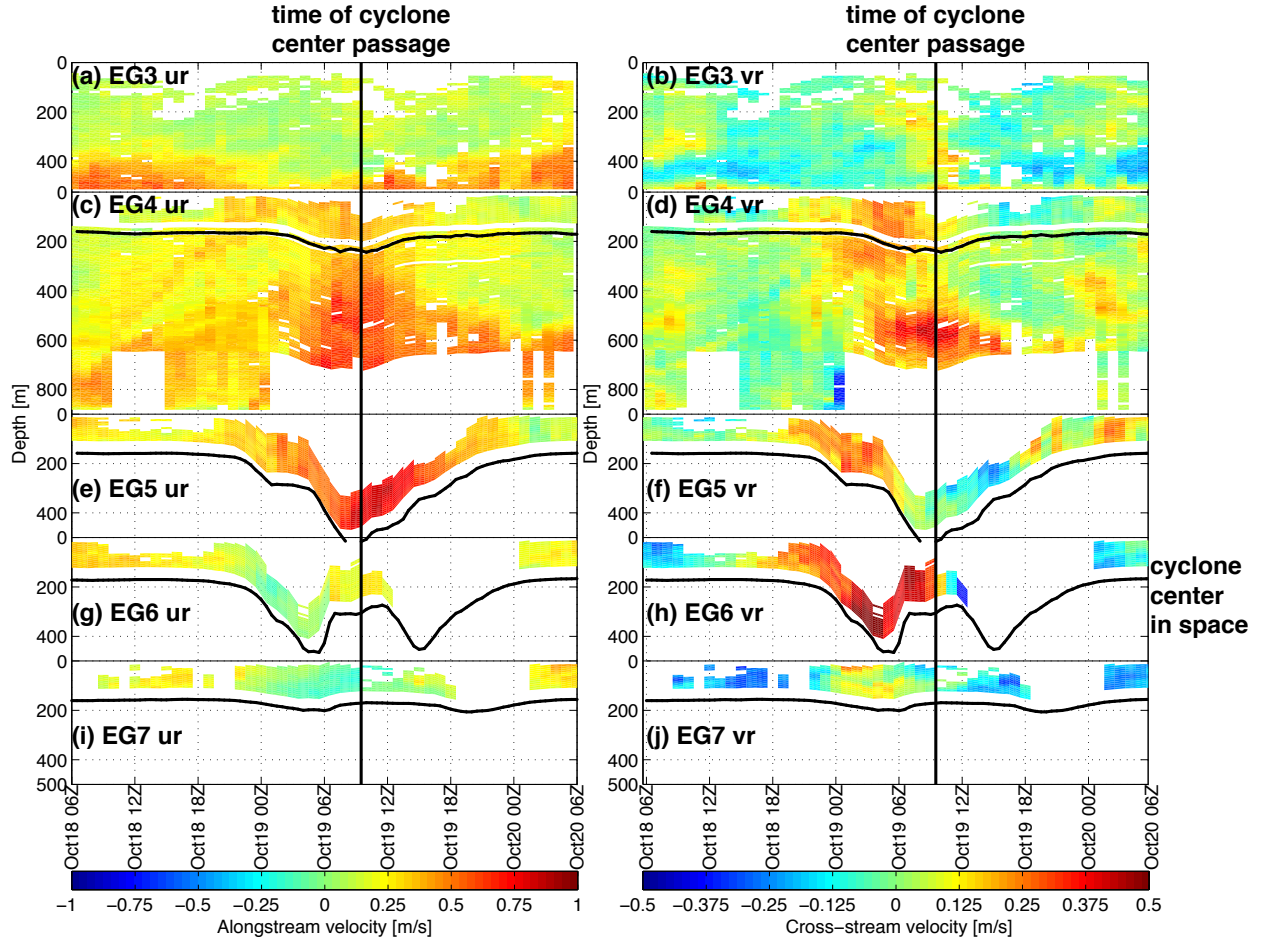

Figure 4: Representative timeseries (from 06Z(06UTC) October 18, 2007 to 06Z October 20, 2007) of velocity (color) and mooring blowdown (black line showing the depth of the top microcat) obtained by the mooring array during the passage of a DSOW cyclone. The left panels show the alongstream velocity, u , measured by the ADCPs on the five moorings on the slope. The right panels show the corresponding cross-stream velocity, v (note the difference in velocity scales). The top panels (a–d) show the full water depth at the moorings (EG3: 525 m, EG4: 900 m). Since there were no ADCP velocity records in the lower part of the water column for the outer three moorings, only the measurements in the top 500 m of the water column are shown in the lower panels (e–j). At 0930Z on October 19, 2007 a cyclone passed onshore of mooring EG6. This time is highlighted with a vertical black line.

Figure 5: Schematic of the flow field when a cyclone translates along the continental slope. The black circle indicates the radius of maximum azimuthal flow.

Figure 6: (a) Histogram of cross-stream distribution of the 190 identified eddies (blue bars) over the 395 days of data. The three bins (onshore, near, and offshore) that are assigned to each mooring are shown by the dashed green lines. (b) Cross-stream bottom depth profile. Mooring locations are indicated.

Figure 7: Timeseries of the 190 identified eddies. (a) Cross-stream location at which the eddies (blue dots) were found. Running means as well as the record mean are shown. (b) Time between successive eddies passing the array.

Figure 8: (a) Top-down view of the full depth-mean flow field (u, v) with the center of the cyclone at $(0, 0)$. The color of the bins is the speed and the black lines show the vector velocity with a 1 m/s scale bar in the top right corner. (b) Background alongstream u_b and cross-stream v_b velocities in the absence of DSOW cyclones.

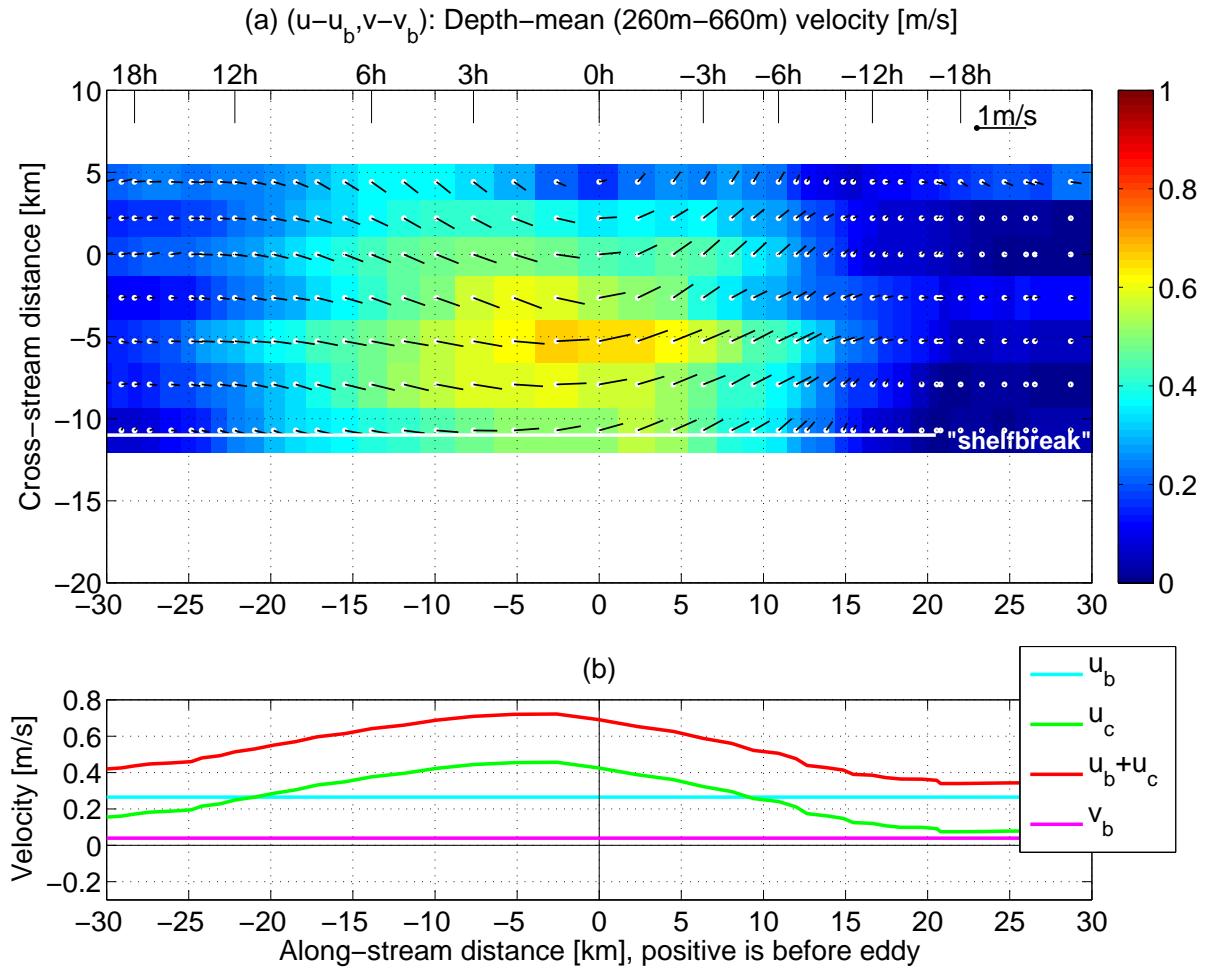

Figure 9: (a) Eddy associated depth-mean flow $(u - u_b, v - v_b)$. (b) Co-translational velocity $u_c(x)$ of the cyclone with respect to the background mean flow and co-translational velocity $u_b + u_c(x)$ with respect to the bottom.

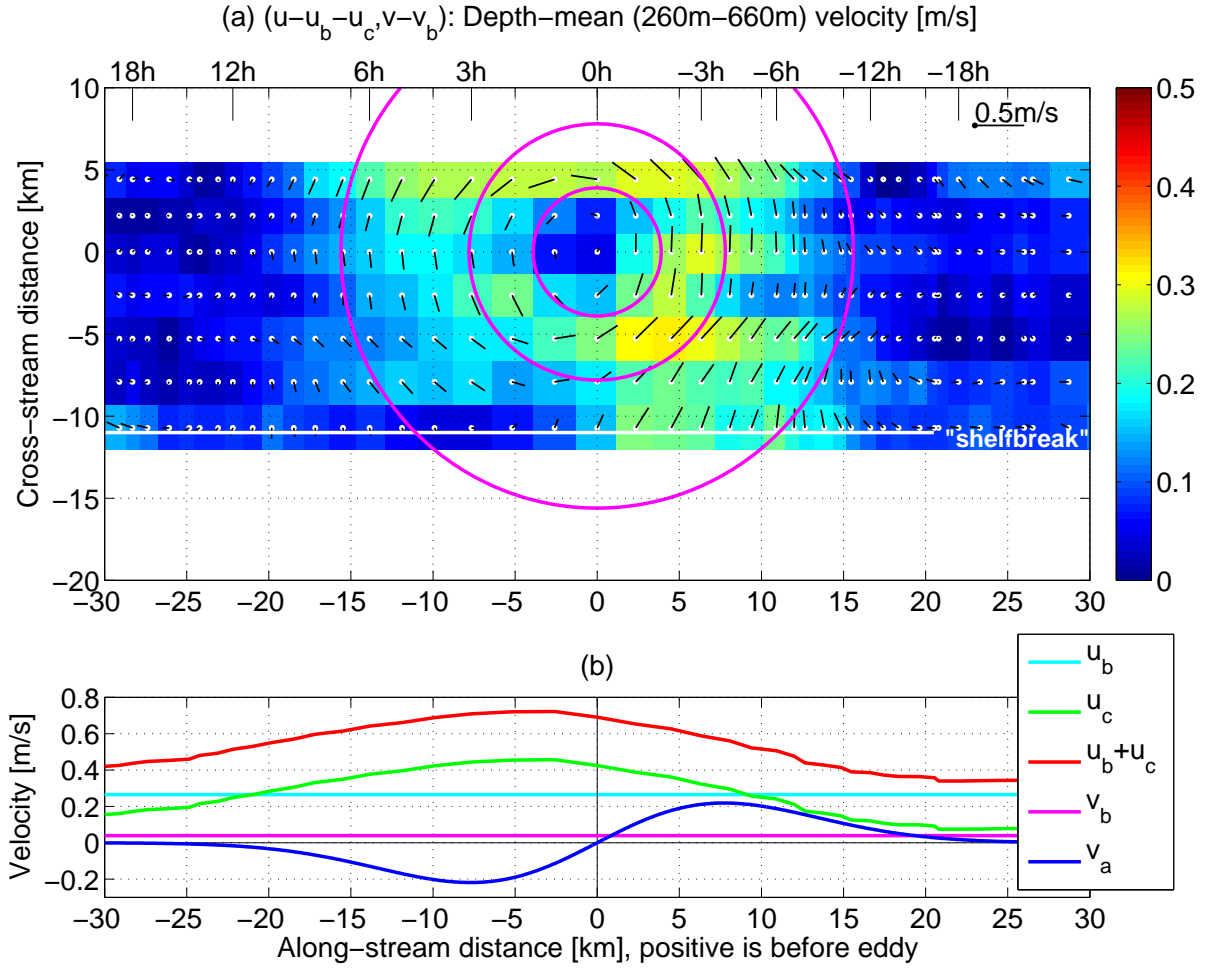

Figure 10: (a) Azimuthal depth-mean flow $(u - u_b - u_c, v - v_b)$ of the cyclone. Note that the color scale and vector velocity scale have been reduced compared to the previous two figures. Concentric circles are included for visual guidance (radii of $0.5R_0$, R_0 , $2R_0$ where $R_0 = 7.8$ km). (b) Azimuthal velocity v_a of the Gaussian eddy fit from Figure 11a.

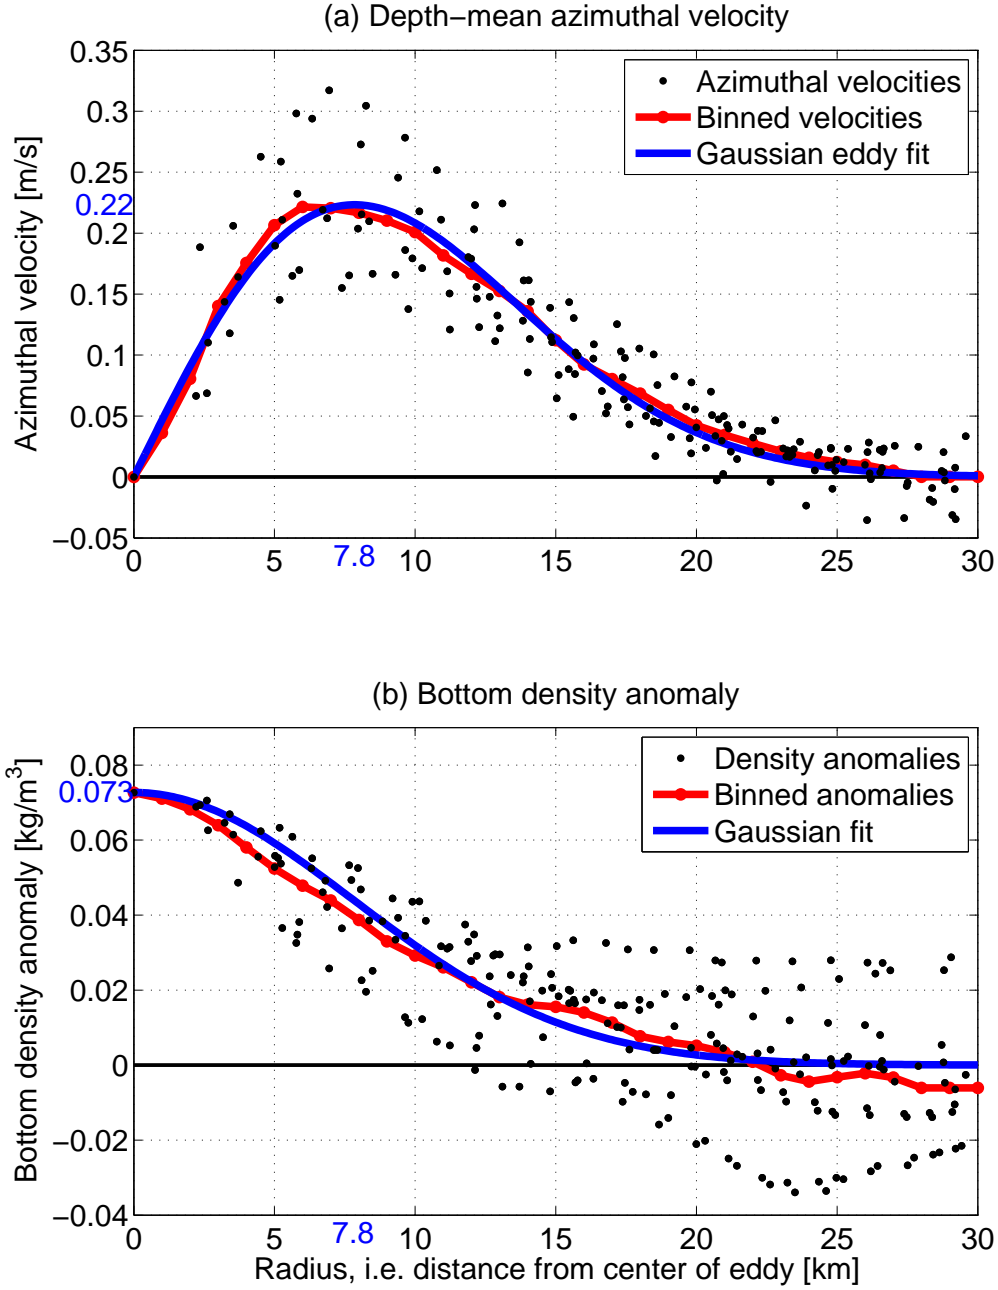

Figure 11: (a) Radial dependance of the azimuthal velocities v_a of the composite eddy. The black dots correspond to bins in Figure 10, the red curve is a smoothed 1 km running mean, and the blue curve is a least squares fit of the Gaussian eddy model to the data. (b) Radial dependence of the bottom density anomaly σ'_e from Figure 12.

Figure 12: (a) Bottom density anomaly σ'_e (color) relative to the background bottom density of 27.735 kg/m³. Velocity vectors are identical to Figure 10. (b) Background bottom density σ_b and density σ_e along center slice ($y = 0$) of cyclone. The classical DSOW definition of 27.8 kg/m³ (Dickson and Brown, 1994) is highlighted.

Figure 13: (a) Vertical structure of the background alongstream velocity at EG4. The fit (blue) is linear where constrained by data and constant elsewhere. The depth-mean (red) is also shown. (b) Vertical structure of the azimuthal velocity v_0 as defined in Equation (4). The fit is quadratic. (c) Vertical structure of the background potential density. The fit is piecewise linear above and below 650 m.

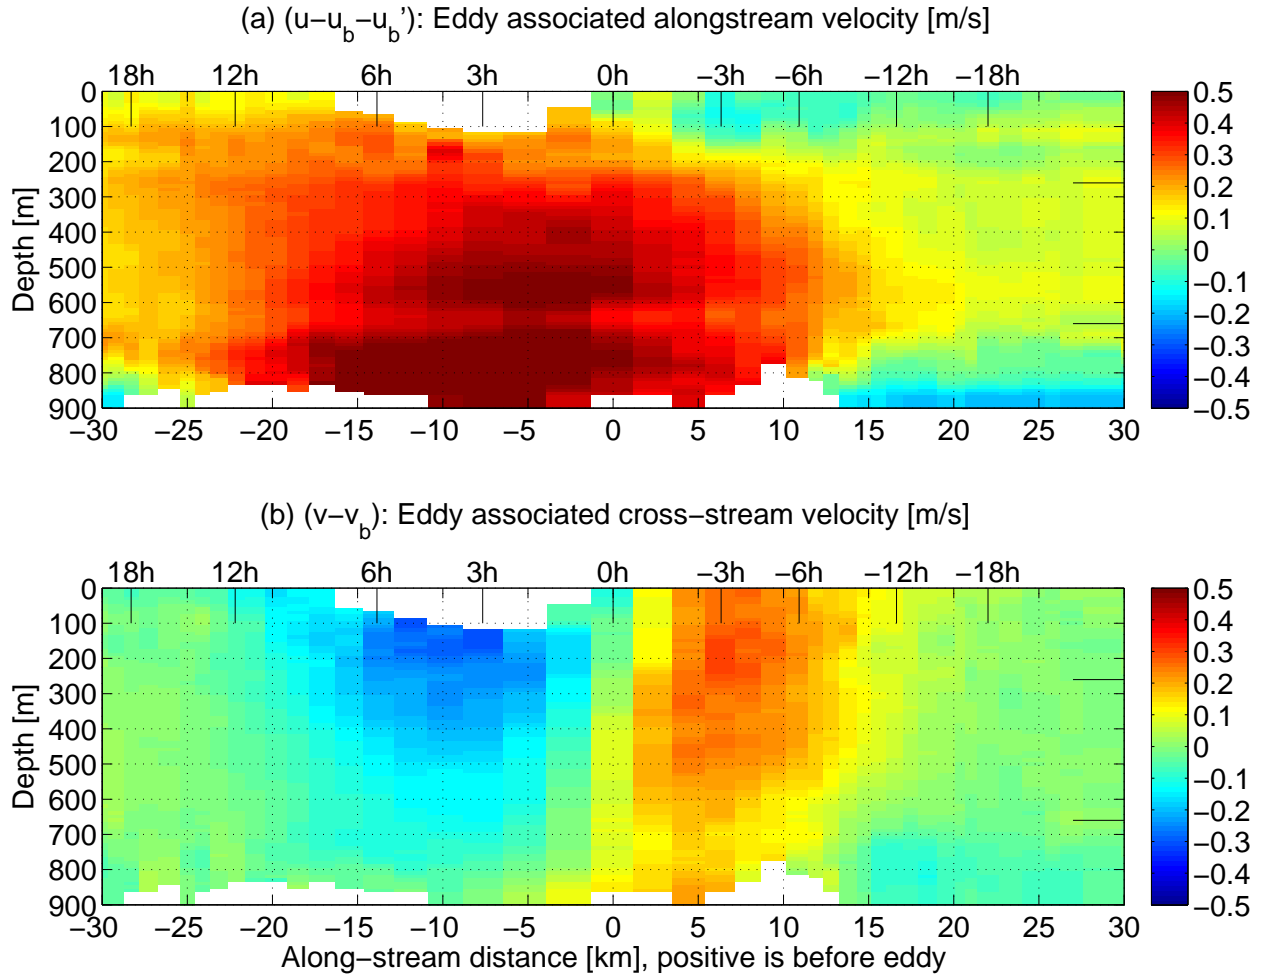

Figure 14: Alongstream section of the eddy associated velocity field of the composite eddy $(u - u_b - u'_b(z), v - v_b)$. The velocities have been averaged in the cross-stream direction from $y = -6$ km to $y = 6$ km.

Figure 15: Mean alongstream section of potential density at EG5 during the passage of 66 cyclones near and onshore of EG4. The horizontal offset from the cyclone centers is 7–10 km. The densities of all available profiles were binned (6 hours temporally, 20 m vertically) and averaged. The bin averages are shown in color (bins containing less than 6 individual profiles are not shown). Lines (magenta for 27.8, white for others) track the height of the isopycnals between temporal bin centers.

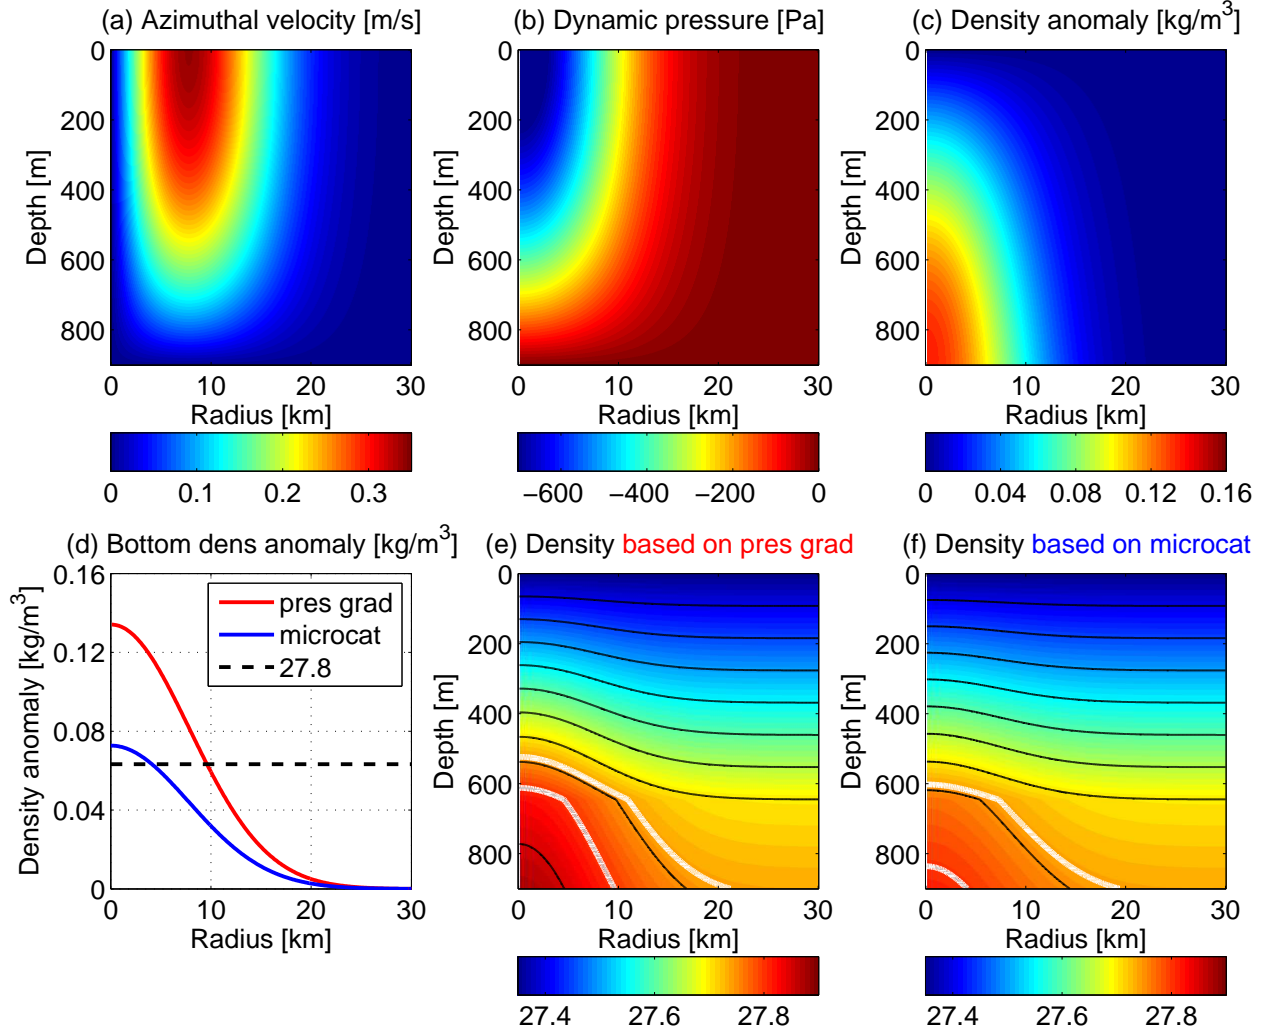

Figure 16: Constructed fields for the calculation of the density field inside smooth fitted DSOW cyclones in the radius-depth plane (see text for methodology). (a) Azimuthal velocity, (b) Dynamic pressure from the horizontal integral of the velocity field, (c) Density anomaly from the vertical derivative of the pressure field, (d) Bottom density anomaly from the pressure gradient calculation shown in (c) and from the fit to the bottom microcat data (Figure 11b); the density anomaly corresponding to a total density of 27.8 is also shown, (e,f) Estimates of the total density [kg/m³] which is the sum of the background profile in Figure 13c and the density anomaly in (c); the 27.8 and 27.74 isopycnals are contoured in white, (e) is an upper estimate using the anomaly field in (c), (f) is a lower estimate using the anomaly field in (c) divided by 1.8 which is the ratio of the two amplitudes in (d).

Figure 17: Location of the 6°C sea surface temperature isotherm indicating the East Greenland/Irminger Current front. The 63 individual realizations (blue) during September 2007 to October 2008 and their mean ± 1 standard deviation (red) are shown as are the (500, 1000, 1500, 2000) m isobaths and the mooring locations (black stars).

Figure 18: Propagation of the 40 SST disturbances that were trackable (speed [m/s] is shown in color). Non-trackable disturbances are shown in black. Each dot refers to an observation of the center of a SST disturbance from a partially cloud free SST image; the time between consecutive dots is not systematic.

Table 1: Summary of DSOW cyclone statistics. The statistics of the SST disturbances described in Bruce (1995) are contrasted with the DSOW cyclone values obtained from the subsurface mooring array in this study.

		Bruce (1995)		this study	
Variable	Name	Mean	Method	Mean	Method
$u_t + u_b$	Translational speed	0.27 m/s ± 0.11 m/s	n = 33, feature tracking in SST	0.72 m/s	n = 101, composite eddy velocities
R_0	Radius	17 km	n = 46, spiral dimensions in SST	7.8 km	n = 101, composite eddy velocities
v_a	Peak azimuthal velocity			0.22 m/s	n = 101, composite eddy velocities
D	Distance between features	54 km	n = 54, features in same SST image	130 km	$D = (u_t + u_b) * T$
T	Time between features	2.3 days	$T = D / (u_t + u_b)$	2.1 days	n = 190, eddy center identification
α'	Feature descent rate	2.3 m/km	n = 35, center locations along slope	2.7 m/km	$\alpha' = \frac{v_b}{u_t + u_b} \frac{dH}{dy}$
